

EX1 – String Pattern Matching Algorithm

Background:

String pattern matching algorithms are very useful for several purposes, like simple search for a pattern in a text or looking for attacks with predefined signatures.

We will implement a dictionary-matching algorithm that locates elements of a finite set of strings (the "dictionary") within an input text. It matches all patterns "at once", so the complexity of the algorithm is linear in the length of the patterns plus the length of the searched text plus the number of output matches.

Since all matches are found, there can be a quadratic number of matches if every substring matches (e.g. dictionary = a, aa, aaa, aaaa and input string is aaaa).

The algorithm matches multiple patterns simultaneously, by first constructing a Deterministic Finite Automaton (DFA) representing the patterns set, and then, with this DFA on its disposal, processing the text in a single pass.

Specifically, the DFA construction is done in two phases. First, the algorithm builds a DFA of the patterns set: All the patterns are added from the root as chains, where each state corresponds to one symbol. When patterns share a common prefix, they also share the corresponding set of states in the DFA.

The edges of the first phase are called *forward transitions*.

The edges of the second phase are called *failure transitions*. These edges deal with situations where, given an input symbol b and a state s , there is no forward transition from s using b . In such a case, the DFA should follow the failure transition to some state s' and take a forward transition from there. This process is repeated until a forward transition is found.

The following DFA was constructed for patterns set {E, BE, BD, BCD, CDBCAB, BCAA}. Solid black edges are forward transitions while red scattered edges are failure transitions.

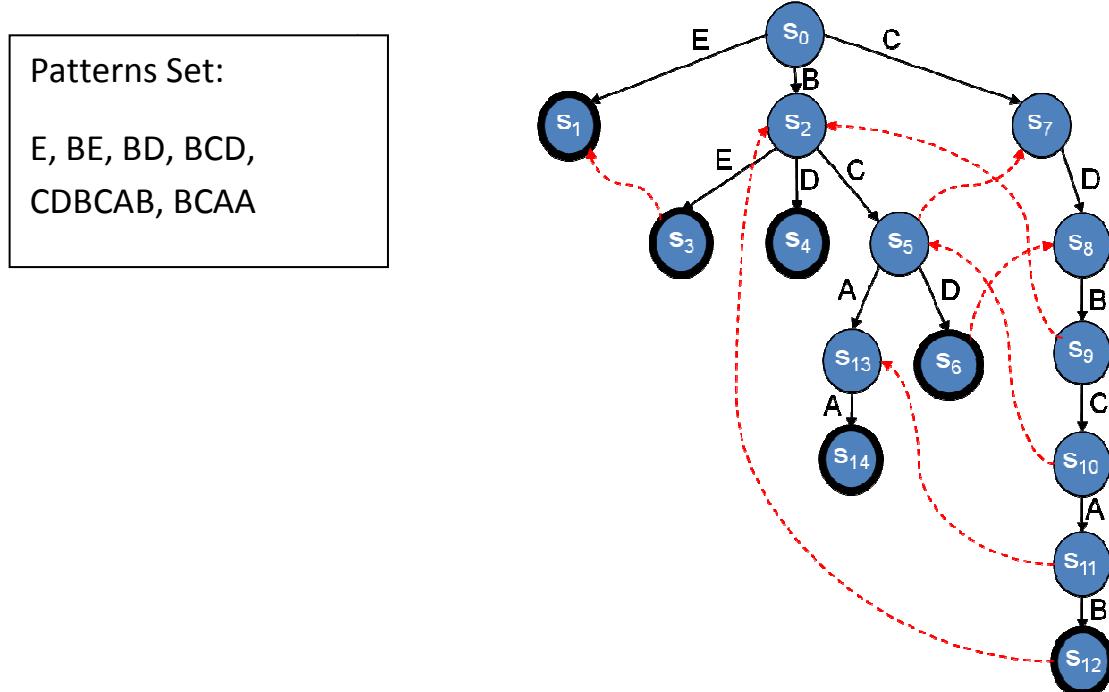

$L(s)$ - the *label* of a state s , is the concatenation of symbols along the path from the root to s .

$d(s)$ - the depth of a state s , is the length of the label $L(s)$.

The failure transition from s is always to a state s' , whose label $L(s')$ is the longest suffix of $L(s)$ among all other DFA states.

The DFA is traversed starting from root. When the traversal goes through an *accepting state*, it indicates that some patterns are a suffix of the input; one of these patterns always corresponds to the label of the accepting state.

Finally, we denote by $scan(s, b)$, the AC procedure when reading input symbol b while in state s ; namely, transiting to a new state s' after traversing failure transitions and a forward transition as necessary, and reporting matched patterns in case $s'.output \neq emptyset$. $scan(s, b)$ returns the new state s' as an output.

Program Description and What You Need to Do:

The algorithm operation:

Let $K=\{y_1, y_2, \dots, y_k\}$ be a finite set of strings which we shall call keywords and let x be an arbitrary string which we shall call the text string.

The behavior of the pattern matching machine is dictated by three functions:

1. a *goto* function g - maps a pair consisting of a state and an input symbol into a state or the message fail
2. a *failure* function f - maps a state into a state, and is consulted whenever the *goto* function reports fail
3. an *output* function $output$ - associating a set of keyword (possibly empty) with every state

Constructing the FSM:

1. Determine the states and the *goto* function
2. Compute the failure function
3. Output function start at first step, complete at the second step

Determine the states and the goto function

Input: set of keywords $K=\{y_1, y_2, \dots, y_k\}$

Output: the *goto* function g

```
Begin
    newstate = 0;
    For i=1 until k do enter(yi)
        For all b such that g(0,b)=fail, do g(0,b)=0
End
```

```
Procedure enter(b1, b2, ... bm):
Begin
    state=0; //root
    j=1
    while g(state,bj) != fail do begin
        //there is an edge for that symbol in the FSM
        state = g(state,bj)
        j = j + 1
    end
```

```

for p=j until m do begin
    // creating states for the rest of the symbols
    newstate = newstate+1
    g(state, bp) = newstate
    state = newstate
end
output(state) = {b1, b2, ... bm}
end

```

Compute the failure function

Input: goto function g, and output function output.

Output: failure function f and output function.

Begin

```

Queue ← empty
//insert to the queue all the states with depth 1
For each b such that g(0,b)=s!=0 do
Begin
    Queue.enqueue(s)
    f(s)=0
End
While queue != empty do
Begin
    //Let r be the next state in queue
    r = Queue.dequeue()
    For each b such that g(r,b)=s!=fail do
    Begin
        Queue.enqueue(s)
        state = f(r)
        While(g(state,b)=fail) do state=f(state)
        f(s)=g(state,b)
        output(s)=output(s) ∪ output(f(s))
    End
End
End

```

Searching for patterns in a given text.

Input: The DFA, text,
Output: positions of all matches, Patterns and output state.

```
Begin
    List matched_list;
    For j=0 to length do
        State = 0;
        While g(state,aj)=FAIL
            State=f(state)
        State = g(state, string[j]);
        If(state.output.size > 0)
            Add matched patterns from state.output to
            matched_list.
    Return matched_list
end
```

Printing to stdout

While constructing the tree:

Each time you create new state in the FSM print: "Allocating state i\n"

Each time you create an edge for the goto function from state i to state j in the FSM
print: "i -> a -> j\n", where 'a' is the character that generate this edge.

Each time you create an edge for the failure function from state i to state j in the FSM
print: "Setting f(i) = j\n"

While searching for patterns in a given text:

For each matched pattern print

"Pattern: y_i , start at: k, ends at: m, accepting state = i"

Where y_i is the matched pattern, k is its start position in the text, m is its end position
in the text and i is the index of the accepting state.

Algorithm interface

You should use pattern_matching.h and slist.h and implement the functions that are
defined there in pattern_matching.c and slist.c respectively. **YOU SHOULD NOT
CHANGE THESE FILES.**

Test your program

In order to test your program, create another file with a main and use the functions in pattern_matching to construct the FSM and search for patterns in a text.

In the example above and the text "xyzabcabde", the output should be:

```
Allocating state 1
0 -> a -> 1
Allocating state 2
1 -> b -> 2
Allocating state 3
2 -> c -> 3
Allocating state 4
0 -> b -> 4
Allocating state 5
4 -> c -> 5
Allocating state 6
5 -> a -> 6
Allocating state 7
0 -> c -> 7
Allocating state 8
7 -> a -> 8
Allocating state 9
8 -> b -> 9
Allocating state 10
1 -> c -> 10
Allocating state 11
10 -> b -> 11
Setting f(2) = 4
Setting f(10) = 7
Setting f(5) = 7
Setting f(8) = 1
Setting f(3) = 5
Setting f(11) = 4
Setting f(6) = 8
Setting f(9) = 2
Pattern: a, start at: 3, ends at: 3, last state = 1
Pattern: abc, start at: 3, ends at: 5, last state = 3
Pattern: bca, start at: 4, ends at: 6, last state = 6
Pattern: a, start at: 6, ends at: 6, last state = 6
Pattern: cab, start at: 5, ends at: 7, last state = 9
```

Error handling

Exit with -1 on any fatal error

What you should submit

ex1.tar containing README, pattern_matching.c and slist.c.
